Dimensional crossover and incipient quantum size effects in superconducting niobium nanofilms

Nicola Pinto  ^{1,2,3}, S. Javad Rezvani ^{1,3}, Andrea Perali  ⁴, Luca Flammia ^{1,5}, Milorad V. Milošević ⁵, Matteo Fretto ³, Cristina Cassiago ³ & Natascia De Leo ³

Superconducting and normal state properties of Niobium nanofilms have been systematically investigated as a function of film thickness, on different substrates. The width of the superconducting-to-normal transition for all films is remarkably narrow, confirming their high quality. The superconducting critical current density exhibits a pronounced maximum for thickness around 25 nm, marking the 3D-to-2D crossover. The magnetic penetration depth shows a sizeable enhancement for the thinnest films. Additional amplification effects of the superconducting properties have been obtained with sapphire substrates or squeezing the lateral size of the nanofilms. For thickness close to 20 nm we measured a doubled perpendicular critical magnetic field compared to its large thickness value, indicating shortening of the correlation length and the formation of small Cooper pairs. Our data analysis indicates an exciting interplay between quantum-size and proximity effects together with strong-coupling effects and the importance of disorder in the thinnest films, placing these nanofilms close to the BCS-BEC crossover regime.

Superconducting niobium thin films are being currently investigated for both fundamental and technological applications. Thin films of Nb, grown on suitable substrates, are needed for technological quantum devices, such as Josephson junctions, nano Superconducting QUantum Interference Devices (SQUIDs)¹, mixers² and single photon detectors³. The fabrication and characterization of high quality Nb nanofilms with optimized superconducting properties is therefore of key importance. These layers can be the ideal platform to design nanostructures with reduced dimensionality, such as single or multiple superconducting nanostripes, to control and enhance superconductivity^{4–7}, to generate multigap and resonant phenomena^{8–13}, to fabricate heterostructures of superconductors with other materials¹⁴, etc. A plethora of these and other novel nanostructures can be fabricated starting from Nb nanofilms, using readily available techniques of, e.g., electron beam lithography and focused ion beam nano-sculpting¹⁵.

In this work we report an extended experimental investigation of the superconducting to normal state transition in Nb nanofilms, with a thickness in the range 9 nm to 90 nm. We have measured and derived the main microscopic parameters characterising the normal and the superconducting state, as the mean free path of charge carriers, the critical current, the magnetic penetration depth and the correlation length. Their values are analysed and discussed in terms of the recent theories. There is some evidence of limitations in the existing models. We have explored the important role of the substrate, depositing films on silicon dioxide (SiO_2) and sapphire (Al_2O_3). These form quite different interfaces with Nb, in terms of oxidation at the interface of the grown nanofilms. Finally, we study the effect of lateral dimension of Nb nanofilms with a view to fabricate superconducting nanostripes in the future.

We find a 3D to 2D dimensional crossover in the superconducting properties of the Nb nanofilms as the thickness is reduced below \approx 25 nm. We see evidence of the dependence of the critical temperature on thickness related

Table 1. The experimentally measured properties of different Nb nanofilms. From left to right: Sample name (an S, following the number, indicates deposition on a sapphire substrate); Film thickness; width of the sample used for the electrical characterisation; T_C ; Superconducting transition width, ΔT_C ; Resistivity at 300 K; Resistivity ratio (RR) at 300 K and 10 K; Perpendicular critical magnetic field at 0 K; coherence length in the film plane at 0 K. For resistivity measurements, 1 μA of current intensity has been sourced to all films but #7 (50 μA); #5 (10 μA and 50 μA) and #6 (50 μA).

to the interplay between quantum size and proximity effects at the substrate interface. In addition, we provide evidence for Cooper-pair shrinking when approaching the ultra thin regime of film thicknesses, that is discussed within the framework of the Bardeen-Cooper-Schrieffer (BCS) - Bose-Einstein Condensation (BEC) crossover theory¹⁶. We demonstrate that the thickness dependence of the mean free path causes the Cooper pair shrinking. This result indicates the non trivial interplay between disorder and BCS-BEC crossover. This interplay is known on the BCS weak coupling side of the BCS-BEC crossover, where disorder increases the superconducting critical temperature and amplifies the superconducting fluctuations¹⁷. Our experimental and theoretical analysis clearly shows that superconducting Nb nanofilms, with thickness between 20 nm and 30 nm, give optimal performance. From a technological point of view, these outcomes fill the gap of information on Nb films, between the atomistic and the mesoscopic range of thickness. They will be useful to guide the fabrication of optimized nanodevices and other superconducting circuitry.

Results

Resistivity and critical temperature. The temperature dependence of the resistivity, $\rho(T)$, of Nb films has been investigated as a function of the thickness, d , in the range $9 \lesssim d \lesssim 80 \text{ nm}$ (see Table 1). For details on fabrication of the films, we refer the reader to the Methods section. The $\rho(T)$ curves shift upward, while the superconducting transition temperature, T_C , decreases as d is progressively reduced (Fig. 1). We have found that for films with $9 < d < 25 \text{ nm}$, the shift of the $\rho(T)$ curves is larger than for $25 \leq d < 80 \text{ nm}$ (Fig. 1). The 80 nm thick film (#6), being least resistive of those measured, exhibits a room temperature (R.T.) value of $\rho(T) \approx 20 \mu\Omega \text{ cm}$, approaching the Nb bulk value ($15 \mu\Omega \text{ cm}$)^{18,19}. Lowering of the resistivity with thicker d suggests a gradual reduction of the film defectivity, in accordance with the behavior reported for Nb films by other groups^{20–22}. For $T_C < T \lesssim 45 \text{ K}$, the $\rho(T)$ shows a plateau, due to the residual defects in the nanofilm (the nature and the influence of which will be discussed later). Starting from the thinnest films, this plateau rapidly shrinks with increasing d up to 25 nm and then attains a nearly constant value for $25 < d < 80 \text{ nm}$ (see inset of Fig. 1).

The gradual improvement of the film quality for larger d is also deduced by the thickness dependence both of the residual resistivity ratio, RRR, here defined as the $\rho(T)$ ratio at $T = 300 \text{ K}$ and $T = 10 \text{ K}$, i.e. $RRR = \rho_{300}/\rho_{10}$ ²³ and the quantity $C = (RRR - 1)^{-1}$, proportional to defects density in the film²¹. RRR grows monotonically with d , from ~ 2 , for $d = 9 \div 13 \text{ nm}$, to ~ 5 at $d = 80 \text{ nm}$ (Fig. 1: inset). These values are comparable with the data reported by Lotnyk *et al.*²³ and, for $d < 40 \text{ nm}$, also with the data of Mayadas *et al.*²⁴. Agreement with findings of Delacour *et al.*²¹ occurs at the lowest thickness ($d \approx 10 \text{ nm}$). Finally, the rapid lowering of C with increasing film thickness indicates reduction of the defect density (Fig. 2), in agreement with findings of ref.²¹. It is worth noting that C

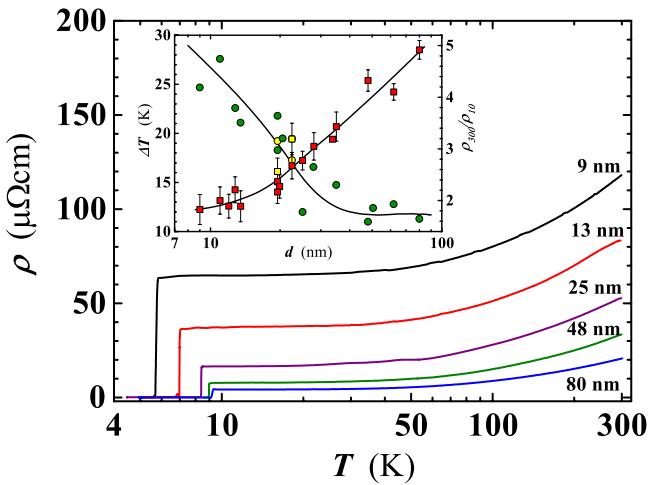

Figure 1. Temperature dependence of the resistivity for selected Nb films, with a thickness ranging from 9 nm to 80 nm. Inset: width of the plateau region (ΔT), above T_C , as a function of d (circles). As ΔT we have considered the T interval corresponding to a film resistivity change of $\pm 2.5\%$ of $\rho(T)$ @ 10 K. Squares: resistivity ratio at $T = 300$ K and at $T = 10$ K as a function of d . All films have been deposited on SiO_2 substrates except those, shown by yellow filled symbols, deposited on sapphire.

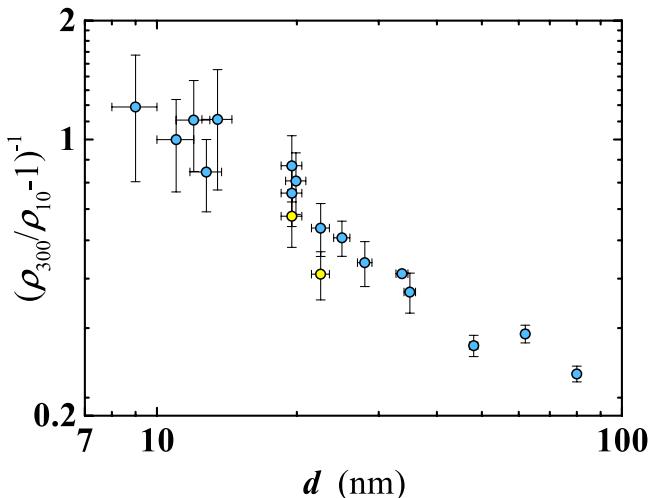

Figure 2. Thickness dependence of the quantity $C = (\rho_{300}/\rho_{10} - 1)^{-1}$. ρ_{300}/ρ_{10} is the residual resistivity ratio (i.e. RRR). All films have been deposited on SiO_2 substrates except for those indicated by yellow filled circles, deposited on sapphire.

becomes lower, for the same thickness, in those films deposited on the sapphire substrate (see Fig. 2). Possible effects of the substrate on other measured film properties will be addressed later.

Residual resistivity (i.e. ρ_{10}) can be used to estimate the charge carriers mean-free path, l , at $T = 10$ K, assuming the constancy of the product $\rho l = 3.75 \times 10^{-6} \mu\Omega \text{ cm}^2$, ρ being the bulk Nb resistivity²⁵. Values for l range from ≈ 1 nm, at the lower thicknesses, to ~ 9 nm at $d = 80$ nm (Fig. 3). Films deposited on sapphire evidence higher l values, in agreement with an expected lower defect density in the film matrix (Fig. 3). Later in our analysis, the thickness dependence of l will be used to extract the thickness dependence of superconducting coherence length and magnetic penetration depth.

Next, we have studied in detail the dependence of the superconducting transition temperature on film thickness. We have determined T_C as the midpoint between temperatures corresponding to the 10% and the 90% of the normal resistance value, located on the residual resistance plateau of the $R(T)$ curve, for $T > T_C$. The difference of those two T values was taken as the width of the superconducting transition, ΔT_C . As expected, T_C decreases with decreasing thickness, from $T_C \approx 9.1$ K for $d = 80$ nm to $T_C \approx 6.5$ K for ≈ 10 nm. For d values lower than ~ 13 nm, T_C decreases more abruptly, with similar T_C values found for our five thinnest films (Fig. 4). Compared to T_C data reported in the literature by other groups, the T_C of our films is somewhat higher for d larger than 17 nm, becoming lower for smaller thicknesses (Fig. 4). This suggests certain level of disorder in our thinnest films. To check that, we examined the width of the superconducting transition, ΔT_C measured as $15 \div 30$ mK, for $25 \leq d < 80$ nm, increasing to

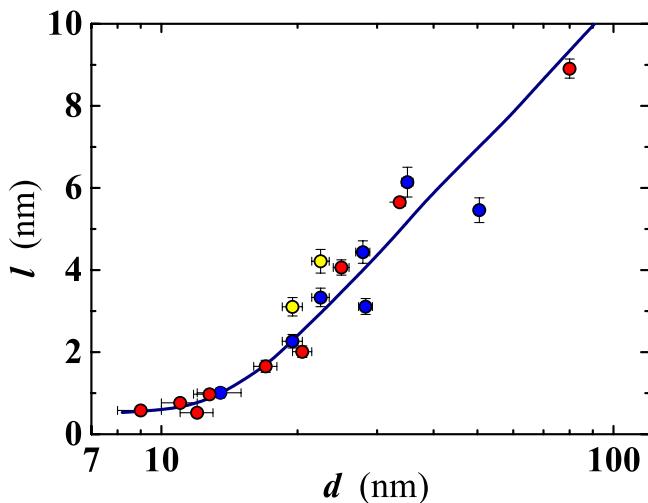

Figure 3. Thickness dependence of the mean free path at 10 K. Data have been derived from the resistivity values measured at the same temperature (i.e. ρ_{10}) for either 10 μm (blue dots) or 50 μm (red dots) wide films. Yellow filled symbols correspond to films (10 μm wide) deposited on a sapphire substrate; all the other films have been deposited on SiO_2 . Continuous line is a guide for eyes.

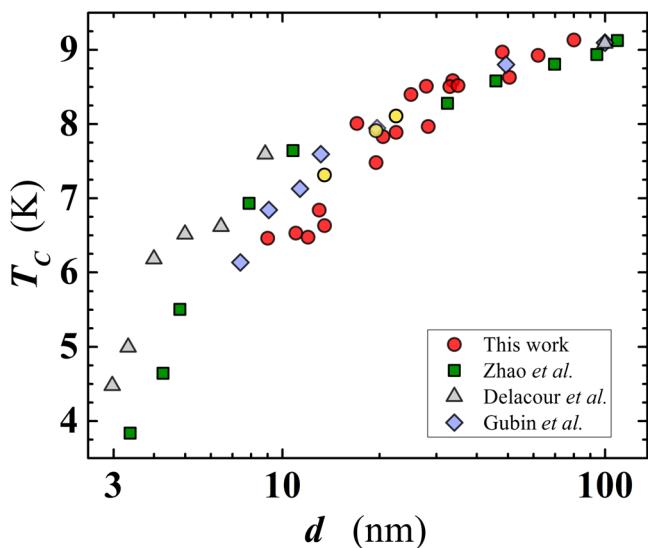

Figure 4. Thickness dependence of the superconducting transition temperature. Circles: data of the present work, for layers deposited on SiO_2 (red filled) and on sapphire (yellow filled). For comparison, we have added data from: Zhao *et al.* (squares)²⁰; Gubin *et al.* (diamonds)²²; Delacour *et al.* (triangles)²¹.

$\simeq 70 \div 80$ mK for the smallest thicknesses ($d < 25$ nm; Fig. 5). Zhao *et al.*²⁰ reported a rapidly rising ΔT_C for $d < 30$ nm, with multiply larger values than those measured in our films with comparable thickness (Fig. 5). These results suggest a superior quality of our superconducting Nb nanofilms at all thicknesses.

What is then the reason for observed lower T_C values for $d < 17$ nm than was the case in ref.²⁰? This is likely an unwanted contribution from an oxidized Nb (i.e. NbO_x) layer²⁶, formed at the interface between the Nb film and the SiO_2 substrate, becoming progressively stronger with the reduction of d . This oxide layer decreases the quality of the film-substrate interface, and reduces the effective Nb film thickness. Such a contribution is largely reduced on sapphire substrates, which could explain the smoother decrease of $T_C(d)$ detected by Zhao *et al.*²⁰. To verify this, we carried out a specific check, depositing 13.5 nm, 19.5 nm and 22.5 nm thick Nb films on a sapphire substrate (i.e. #H14S, #H1S and #H11S, respectively). Indeed, in those films T_C was significantly higher (~ 0.5 K of increase of T_C for $d = 13.5$ nm, see yellow filled circles in Fig. 4) than in those deposited on a SiO_2 substrate, obtained during the same run (#H15 & #H1; #H9: see Table 1). The reduction of C and the increase of l , in films deposited on sapphire, is in agreement with the hypothesis of a better quality of the layer at the film-substrate interface.

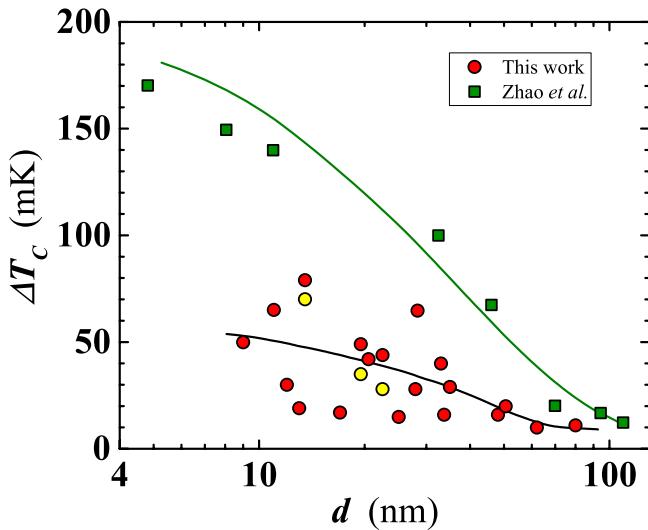

Figure 5. Thickness dependence of the superconducting transition width. Circles: data of the present work, measured in films deposited on SiO_2 (red filled) and on sapphire (yellow filled). Squares: data taken from Zhao *et al.*²⁰. Solid lines serve as a guide for the eyes.

Another likely effect of the formed NbO_x layer is that, being a conductive system of electrons in their normal state, it is able to sink Cooper pairs from the superconducting Nb nanofilm, suppressing the condensate fraction and reducing the T_C via proximity effect. This phenomenon should become more effective as the thickness of the Nb nanofilm is reduced so that NbO_x layer becomes a sizeable fraction of the Nb film thickness. Indeed, the $T_C(d)$ curve of Fig. 4 shows a smooth decrease of T_C for intermediate-to-large film thickness (i.e. for $20 \lesssim d \lesssim 80$ nm), which accelerates for smaller d values (i.e. at $d \lesssim 20$ nm). The T_C suppression law, due to the proximity effect, has been derived by McMillan²⁷ and is given by:

$$T_C = T_{C0} \left(\frac{3.56 T_D}{T_{C0} \pi} \right)^{-\alpha/d}, \quad (1)$$

where $\alpha = d_N N_N(0)/N_S(0)$ is an effective thickness of the conductive layer at the interface; $T_{C0} = 9.22$ K is the bulk T_C of Nb and $T_D = 277$ K is the Debye temperature. The quantities $N_N(0)$ and $N_S(0)$ are the density of states in the normal (N) and superconducting (S) layers, respectively. For simplicity, considering the ratio $N_N(0)/N_S(0)$ equal to unity, one obtains $\alpha \cong d_N$. Delacour *et al.*²¹ applied Eq. (1) to fit their data set for $T_C(d)$ of Nb films on sapphire, finding a very small effective thickness of the normal layer of $d_N = 0.54 \pm 0.02$ nm. Following the same procedure and interpretation of Delacour *et al.* we obtain a satisfactory fit of our data for $T_C(d)$ using Eq. (1) and $d_N = 0.96 \pm 0.04$ nm (Fig. 6). In addition, we have found an intermediate value of $d_N = 0.76 \pm 0.03$ nm for the $T_C(d)$ data set of Zhao *et al.*²⁰ for films also on sapphire. We conclude that the obtained thickness of NbO_x in our case (~ 1 nm) is reasonable, being comparable but larger than found in films grown on sapphire. This analysis confirms the important role played by the substrate. In particular, the absence of reactive oxygen, especially onto the substrate surface, is a mandatory requirement to deposit ultra-thin and ultra-clean Nb films, avoiding or drastically limiting the formation of a metallic oxide at the film-substrate interface.

At this point it is worth noting that in the presence of an overall suppression of $T_C(d)$ due to proximity effect, the fitting function given by Eq. (1) can be subtracted from the general data set in order to amplify the visibility of the remaining oscillations of T_C for decreasing d . Namely, in this range of thicknesses, one expects that T_C starts to display oscillations due to proliferating quantum size effects and shape resonances associated with confinement effects in the perpendicular direction. We have applied the aforementioned subtraction to our $T_C(d)$ data, but also to the data of Delacour *et al.*²¹ and Zhao *et al.*²⁰ where such oscillations were not considered. Remarkably, in all cases we detected residual T_C oscillations of increasing amplitude for decreasing d (shown in Fig. 7). The observed increase of oscillations could be attributed to an incipient effect of the shape resonances when $d < 20$ nm. Namely, the detected oscillations of T_C with amplitude of 5% in the thinnest films are very much comparable to the theoretical predictions for Al and Pb films of similar thickness, discussed in ref²⁸ (and references therein), suggesting their quantum-confinement origin in our Nb nanofilms. As should be the case, for larger thicknesses ($d > 20$ nm) the T_C oscillations in our films get progressively reduced in amplitude.

As the final characterization of the critical temperature in our films, we discuss the recent findings of Ivry *et al.*²⁹ that T_C should exhibit an intricate dependence not only on the film thickness but also on the sheet resistance, R_S . Namely, Ivry *et al.* demonstrated a universal relationship among T_C , d and R_S , for films with thicknesses in a broad range (i.e. $\approx 1 \div 10^3$ nm) and belonging to different classes of superconducting materials²⁹, showing that experimental data can be well described by the relation:

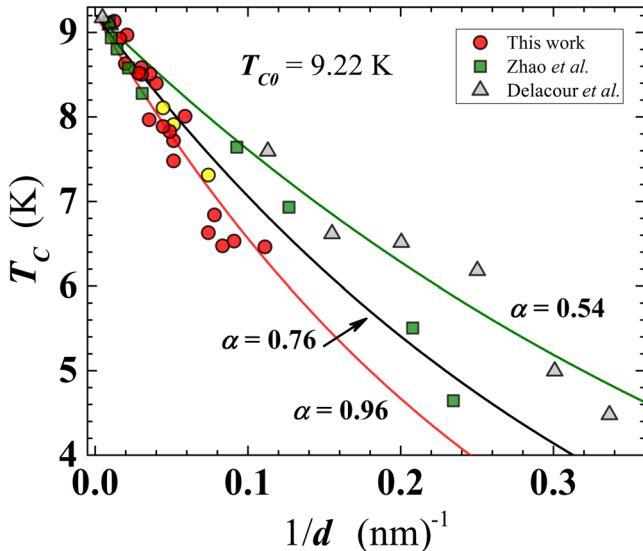

Figure 6. Superconducting transition temperature as a function of the reciprocal film thickness. Present work (SiO_2 substrate: red filled circles; sapphire substrate: yellow filled circles); Zhao *et al.*²⁰ (triangles); Delacour *et al.*²¹ (squares). Continuous lines are least-squares fit, using Eq. (1) (see text), of the different data sets. The effective thickness of the normal layer (in nm) is represented by the corresponding α value for each curve.

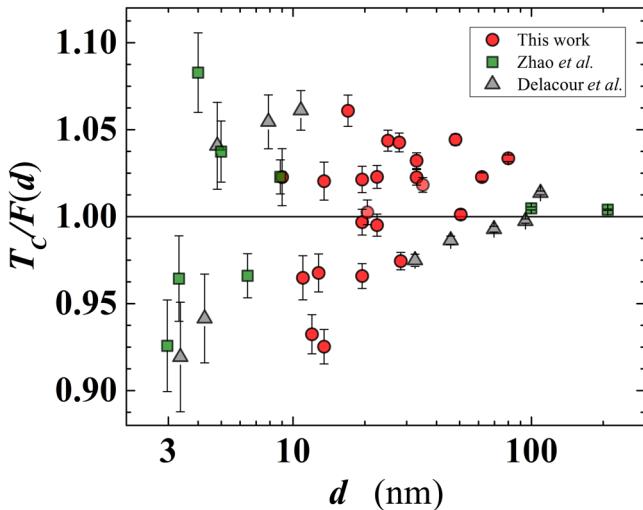

Figure 7. Plot of the ratio $T_c/F(d)$ (see text) as a function of the film thickness for several Nb data sets. The fitting function, $F(d)$, has been calculated using the theoretically expected value of the Nb bulk transition temperature (i.e. $T_{c0} = 9.22$ K). Circles: present work; triangles: Zhao *et al.*²⁰; squares: Delacour *et al.*²¹. The error bars are defined by Eq. (S7) of the supplementary information.

$$d \cdot T_c = AR_S^{-B}, \quad (2)$$

where A and B are fitting parameters, hereafter considered unitless. We have therefore investigated the behavior of T_c in our films as a function of R_S , to test the validity of Eq. (2). Figure 8 shows the very successful fit, yielding $A = 1350 \pm 120$ and $B = 0.76 \pm 0.05$. Our B value is in excellent agreement with the result of Ivy *et al.* for Nb films, while our parameter A is larger^{29,30}. This fact, in addition to the better quality of our nanofilms, is also due to the different range of data points used for the fit compared to those considered in ref.²⁹. The inset of Fig. 8 shows that in our case T_c steeply decreases for $0 < R_S \lesssim 20 \Omega/\square$, and then attains an almost constant value for $R_S > 50 \Omega/\square$.

Other critical quantities and characteristic length scales of the superconducting state. Additional information about the physical properties exhibited by the here investigated Nb films can be extracted from the behavior of the critical current density, J_C , and the maximal magnetic field the superconducting samples can sustain, i.e. the

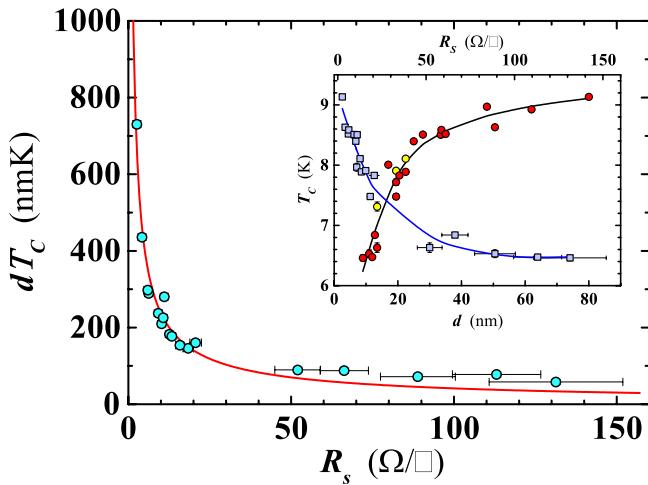

Figure 8. Dependence of the product of the film thickness, d , and the superconducting transition temperature, T_C , on the sheet resistance (R_s) for the investigated Nb nanofilms. The red line is the least-squares fit of the data obtained using Eq. (2). Inset reproduces the behavior of T_C (circles) and of R_s (squares) as a function of the thickness. Yellow filled symbols refer to samples deposited on sapphire substrates. Blue and black lines are guides for the eyes.

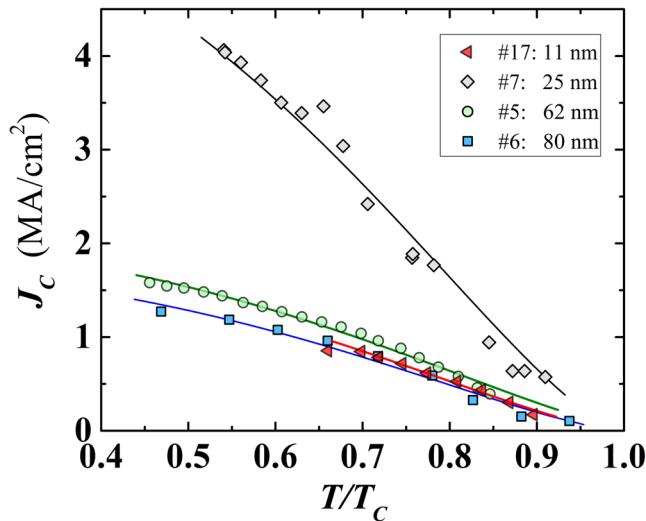

Figure 9. Normalised temperature dependence of the critical current density. Plotted curves refer to four films covering the whole range of thicknesses of the considered Nb nanofilms. Lines are the least-squares fit by the Ginzburg-Landau relation (see the equation S1 in the supplementary material) to the experimental data points.

upper critical magnetic field H_{c2} . We measured the critical current at different fixed temperatures and in absence of any applied magnetic field. We assumed as critical current the lowest I value causing the jump into the normal state in the I-V curve. The uncertainty in the critical current values was less than 1% (see the supplementary information and Figure S2). The aim is to obtain the functional temperature dependence of these quantities and then extrapolate their values at zero temperature. The dependence of the critical current density, J_C , on reduced temperature, $t = T/T_C$, for selected films (representative of all investigated ones), is shown in Fig. 9. To model the measured $J_C(t)$ behaviour, we rely on the Ginzburg-Landau (GL) theory, although it is formally valid only near T_C . However, to recover the experimentally well-known temperature dependence of thermodynamic critical field $H_c \propto (1 - t^2)$ (as opposed to $H_c \propto (1 - t)$ in standard GL theory), we employ the empirical modifications proposed by Ginzburg³¹ (also corresponding to the temperature dependence from a two-fluid model), as already successfully used in theoretical descriptions of single-crystalline superconductors even far below T_C ³². As a consequence of these modifications, the GL parameter $\kappa = \lambda/\xi$ (where λ is the penetration depth and ξ the coherence length) becomes temperature dependent $\kappa(T) = \kappa(0)/(1 + t^2)$, the upper critical field exhibits dependence $H_{c2} \propto (1 - t^2)/(1 + t^2)$, and the depairing current density becomes proportional to $(1 - t^2)(1 - t^4)^{1/2}$. For more details, we refer the reader to supplementary material.

In absence of an applied magnetic field, the measured critical current density should (nearly) correspond to the depairing current density. Assuming the above modified GL behavior of $J_C(T)$, we performed the fitting of the

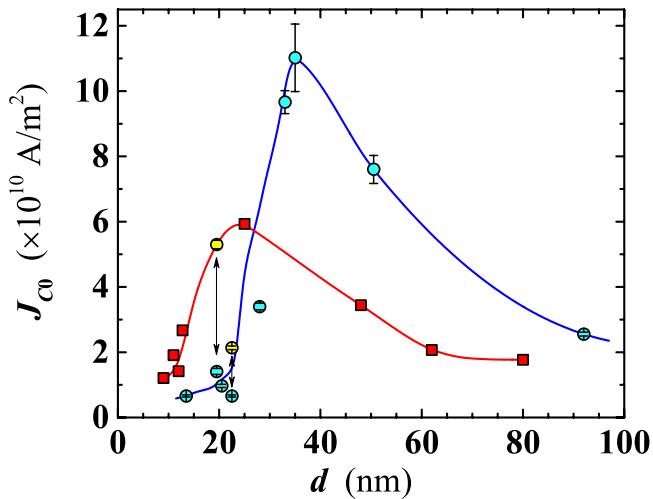

Figure 10. Thickness dependence of the critical current density extrapolated at 0 K. Circles: films $w = 10 \mu\text{m}$ wide; yellow filled symbols correspond to the films deposited on sapphire substrates. Squares: $w = 50 \mu\text{m}$ wide. The two lines are guides for the eyes.

obtained data to extract J_{c0} for films of different thicknesses, having a lateral width of either $w = 10 \mu\text{m}$ or $w = 50 \mu\text{m}$. We found a strong dependence of J_{c0} on both the thickness and the width. It turns out that, compared to the Nb bulk J_{c0} value of 1.96 MA/cm^2 , our films exhibit considerably higher J_{c0} for thickness in the range $13 < d < 60 \text{ nm}$, with a peak value ~ 3 and ~ 5.5 times higher for sample width $w = 50 \mu\text{m}$ and $w = 10 \mu\text{m}$, respectively (see Fig. 10). The sizeable increase of J_{c0} upon narrowing the film width is related to the edge barrier effects for vortex entry, as observed also by Il'in *et al.*³³. Effects of the film geometry on J_c are expected when the penetration depth becomes comparable to any dimension of film cross-section (d or w), at the crossover between depinning and depairing mechanism for the critical current. In addition, the increase of J_{c0} in nanofilms deposited on sapphire evidences once more the important role played by this substrate in improving the superconducting properties of the nanofilms.

The measured critical current densities allow to estimate the penetration depth λ of the Nb nanofilms as a function of d . For type-II superconductors with thickness smaller than λ ($2d < \lambda$), holds the relation of Talantsev and Tallon³⁴:

$$J_C^{II}(sf) = \frac{H_{C1}}{\lambda} = \frac{\Phi_0}{4\pi\mu_0\lambda^3}(\ln\kappa + 0.5), \quad (3)$$

where Φ_0 is the magnetic flux quantum; μ_0 the vacuum permeability and $\kappa = \lambda/\xi$ generally assumed to be ≈ 1 for Nb in the clean limit. $J_C^{II}(sf)$ represents the current density which generates the self field that induces vortices and itself limits the maximal current in absence of any applied magnetic field. Therefore, under the above mentioned condition, the critical current density is determined only by the fundamental lengths of the superconducting state λ and ξ , and is independent of geometry and detailed pinning microstructure. Applying Eq. (3) to the measured values of the critical current density we have extrapolated the values of λ at the lowest accessible T by the experimental setup ($\approx 4 \text{ K}$). The resulting thickness dependence of λ is shown in Fig. 11 together with the λ values measured in Nb films by Gubin *et al.*, using a resonance technique²². The agreement between our data and those of ref.²² is very good up to $d \approx 25 \text{ nm}$, with an increasing discrepancy for $d \approx 50 \text{ nm}$. An alternative check of the thickness dependence of λ has been done by using the experimental mean free path l (Fig. 3) and the relation valid in the dirty limit³⁵:

$$\lambda = 0.62\lambda_L \sqrt{\left(\frac{\xi_0}{l}\right)}, \quad (4)$$

where $\lambda_L = 39 \text{ nm}$ and $\xi_0 = 38 \text{ nm}$ are the Nb bulk value of the London penetration depth and the BCS coherence length, respectively. For thinner films ($d \lesssim 20 \text{ nm}$) the values of λ calculated either by Eq. (4) or Eq. (3) are comparable while diverging, in values and behaviour for thicker films. While λ calculated by Eq. (4) preserves the likely correct d dependence and decreases towards the bulk limit, its values are more than halved with respect to those obtained in ref.²². The apparent disagreement in our $\lambda(d)$ data calculated by the two methods, can be accounted for considering that Eq. (3) is valid for $2d \ll \lambda$ ³⁴, condition that appears to be fulfilled in our case only below $d \approx 20 \text{ nm}$ (Fig. 11). Finally, it is worthwhile to consider also the dependence of λ on the value of κ in Eq. (3), considering that much larger values of the GL parameter are expected in dirty films compared to single-crystalline samples. Figure 11 reproduces also the possible range of values taken by λ for $1 \leq \kappa \leq 20$ in the thickness range $10 < d < 50 \text{ nm}$. Looking at Fig. 11 it is evident that assuming $\kappa \approx 1$ (as was actually done in ref.³⁴) a better agreement between the two calculation methods of λ would have been found.

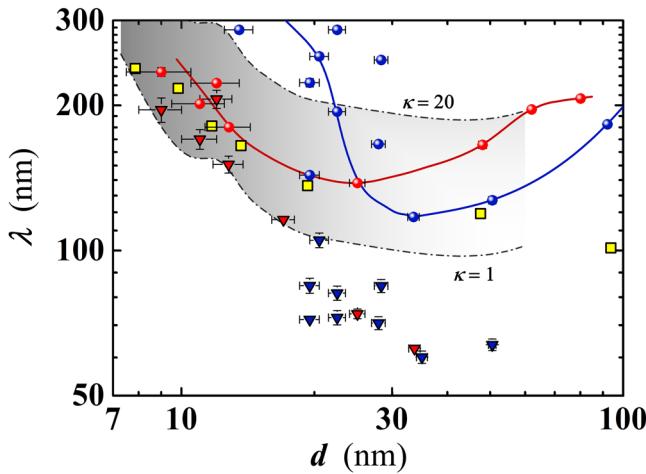

Figure 11. Penetration depth as a function of the Nb film thickness. Values have been calculated by using both Eq. (3), with $\kappa = 2.2$ (spheres), and Eq. (4) valid in the dirty limit (triangles). Shown data refer to films having width $w = 10 \mu\text{m}$ (blue) or $w = 50 \mu\text{m}$ (red). Squares: values measured by Gubin *et al.*²². Dash and dotted lines delimit the range of λ variation (for the case $w = 50 \mu\text{m}$), for κ varied between 1 (bottom line) and 20 (top line) in Eq. (3). Continuous lines are guides for the eyes.

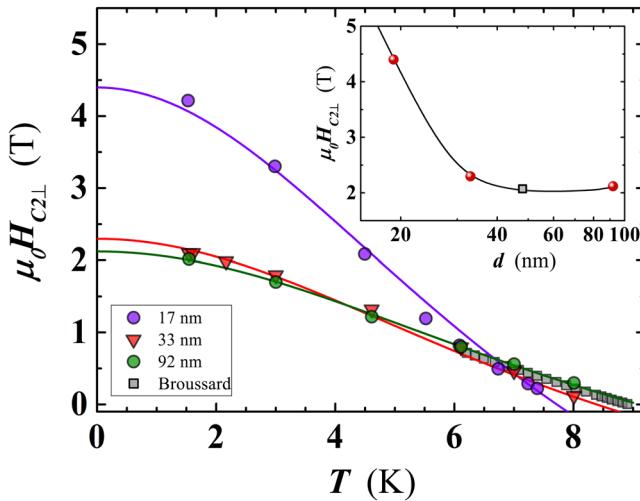

Figure 12. Temperature dependence of the perpendicular critical magnetic field ($H_{c2\perp}$). For each temperature, the corresponding $H_{c2\perp}$ value has been derived as the mean value of the applied magnetic fields corresponding to 10% and 90% of the resistivity value at the saturation point (see Figure S3 in supplementary material). Lines are the least-squares fit of the data points by Eq. (5). For comparison, data of Broussard³⁸ for the $H_{c2\perp}$ of a 48 nm thick Nb film have been added to the plot. Inset: thickness dependence of $H_{c2\perp}$ at 1.6 K, for the three investigated Nb films (spheres) and for the sample of Broussard³⁸ (square) whose value, at 1.6 K, has been extrapolated by Eq. (5) from the experimental data available down to ≈ 6 K. The black line serve as a guide for the eyes.

Finally, we have also studied the temperature dependence of the perpendicular critical magnetic field, $H_{c2\perp}$, for three Nb nanofilms having a thickness of 19.5 nm, 33 nm and 92 nm (#H1, #H8 and #H12, respectively). The $H_{c2\perp}$ value has been determined by measuring the resistivity as a function of the applied magnetic field, at different fixed T (Figure S3 in supplementary material). The experimental $H_{c2\perp}(T)$ curves for the three films are reproduced in Fig. 12. At a fixed T , the $H_{c2\perp}(T)$ has been determined as the average of the two H values corresponding to the 10% and the 90% of the $\rho(H)$ saturation value. The two thicker films (i.e. #H8 & #H12) exhibit practically overlapped curves. Approaching the lowest T , $H_{c2\perp}(T)$ tends to saturate while a small deviation from the linearity has been detected for the thinner film (i.e. #H1) at $T > 5.5$ K. This fact suggests inhomogeneity effects in the film thickness and/or presence of defects due to the reduced d value, that is likely related to an interaction of the Nb film with the SiO_2 of the substrate, as mentioned above in the discussion of the rapid decrease of T_c in that limit. The T dependence of $H_{c2\perp}$ has been captured by a least-squares fit of the experimental values using the relation³⁶:

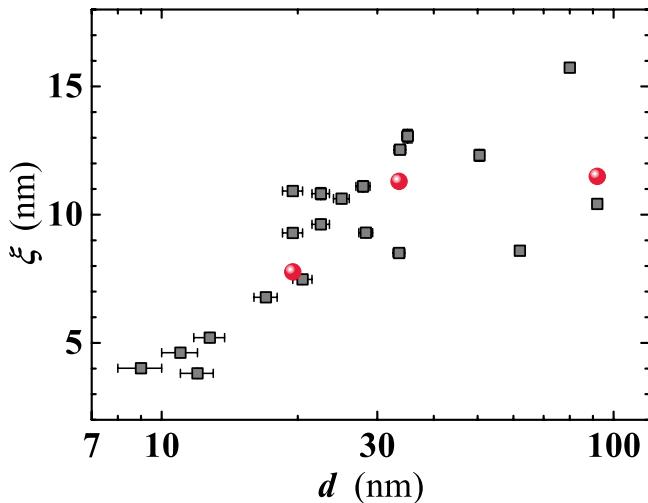

Figure 13. Thickness dependence of the coherence length at zero temperature for investigated Nb films. Squares: values derived by Eq. (7) taking into account the measured mean free path (l). Spheres are the $\xi(0)$ values calculated by the measured $H_{C2\perp}(T)$ and the fitting procedure described in the text.

$$H_{C2\perp}(T) = H_{C20\perp} \frac{[1 - (T/T_C)^2]}{[1 + (T/T_C)^2]}, \quad (5)$$

with $H_{C20\perp}$ being the value of the orthogonal upper critical magnetic field at zero temperature.

The values of $H_{C2\perp}(T)$ allow us to calculate the in-plane coherence length $\xi(T)$ of our films, extracted by the standard GL relation³⁶:

$$H_{C2\perp}(T) = \frac{\Phi_0}{2\pi\xi^2(T)}, \quad (6)$$

The Ginzburg-Landau coherence lengths at $T = 0$ K, $\xi(0)$, for the three samples considered in Fig. 12, have been derived using the Eq. (6) and the $H_{C20\perp}$ values extracted by the Eq. (5). $\xi(0)$ raises from ≈ 7.8 nm for $d = 19.5$ nm to ≈ 11.5 nm for $d \geq 90$ nm (see Table 1), compared to the Nb bulk value of $\xi(0) = 0.74 \xi_0 \approx 28$ nm.

Our results are in agreement with those reported by Trezza *et al.* for Nb films of comparable thickness³⁷, and with values measured by Broussard in a 48 nm thick Nb film³⁸. Figure 12 reproduces the $H_{C2\perp}(T)$ data of ref.³⁸ and shows an overlapping trend with data for our two thicker films, suggesting a saturation of $H_{C2\perp}$ for Nb films with d larger than 33 nm. The hypothesis has been confirmed also by the $H_{C2\perp}(T)$ value of the Broussard film at 1.6 K obtained through a best fit with Eq. (5) (see the inset of Fig. 12).

Finally, the thickness dependence of the superconducting coherence length in our samples has been evaluated using the experimental l values, under the validity of the dirty limit condition:

$$\xi(0) = 0.855 \sqrt{(\xi_0 l)}, \quad (7)$$

where $\xi_0 = 38$ nm is the BCS Nb bulk coherence length. The value of the coherence length at 10 K raises from $\xi = 4$ nm for $d \approx 10$ nm, up to $\xi \approx 13$ nm for $d \approx 35$ nm. For larger thicknesses we observe a saturation effect albeit data points appear somewhat scattered (Fig. 13). In any case, the ξ values calculated by Eq. (7) are in very good agreement with those derived from the $H_{C2\perp}(T)$ measurements (Fig. 13). Finally, we note that, at $d = 19.5$ nm (#H1), $\xi(0) \approx 7.8$ nm evidences presence of smaller Cooper pairs, exhibiting shrinking by a factor of five compared to the bulk value.

Discussion and Conclusions

The comprehensive experimental characterisation of metallic and superconducting properties of Nb nanofilms reported in this work demonstrates two different regimes depending on the thickness. For large thickness, in the range $25 \text{ nm} < d < 80 \text{ nm}$, all measured electrical properties evolve smoothly for decreasing d . The Nb nanofilms are found to be of high quality and superconductivity has a 3D character. Around $d = 25$ nm, normal and superconducting state properties display an abrupt change in their behavior. Below 25 nm of thickness, superconductivity becomes progressively 2D, realizing a 3D-2D dimensional crossover. This dimensional crossover for decreasing thickness results to be particularly evident in the sudden suppression of T_C , in the peaked behaviour of the critical current density and when comparing the evolution of the penetration depth and the correlation length as a function of thickness. Approaching $d = 10$ nm, novel quantum phenomena start to emerge: (i) on top of the overall drop of T_C for decreasing d , remaining oscillations of $T_C(d)$ indicate incipient quantum size effects. (ii) A factor of five enhancement of the penetration depth for the thinnest films with respect to the bulk has been

observed. This points to a strengthening of the type-II magnetic character below 20 nm of thickness. Our measured penetration depth $\lambda(d)$ compares in a satisfactory way with other data of λ , in the range of thickness $d \leq 25$ nm. (iii) A sizeable amplification of the upper critical magnetic field is associated with a considerable shrinking of the Cooper pair size. The thinnest Nb nanofilms are close to the BCS-BEC crossover regime, predicted for very thin nanofilms. Close to $d = 25$ nm the Nb nanofilms show optimized superconducting properties: maximal $J_C \simeq 6$ MA/cm², $\lambda = 150$ nm, $\xi(0) \simeq 10$ nm, $H_{C2\perp}(T) = 2$ T, $T_C = 8$ K, and a narrow superconducting transition of $\Delta T_C = 40$ mK. Therefore, around $d \simeq 25$ nm of thickness, Nb nanofilms constitute an ideal platform for nano-structuring in the form of stripes for the fabrication of nano superconducting devices. In addition, we have shown that the thickness dependence of the mean free path of the carriers plays a crucial role in understanding the thickness dependence of the superconducting properties, mainly in the penetration depth and in the coherence length. The effects of disorder are therefore entangled with the dimensional crossover and with the BCS-BEC crossover occurring below few tens of nanometers. Finally, we have found that the amplification effects of the superconducting properties reported in this work depend on the substrate and on the lateral width of the nanofilms. Optimal superconducting properties have been demonstrated using sapphire as a substrate and squeezing the lateral size of the nanofilms toward few micrometers, furthermore suggesting great potential in the fabrication of superconducting nanostripes of Nb at the nanometer scale.

Methods

Niobium nanofilms have been deposited at room temperature on thermally oxidized Si wafer (silicon oxide thickness: 300 \div 500 nm), by an ultra high vacuum DC sputtering system, in a base pressure of about 2×10^{-9} mbar. Film thickness has been varied from about 9 nm to 90 nm, keeping constant the deposition rate at 0.65 nm/s (see Table 1). Scanning electron microscopy (SEM) analysis has been carried out on some films by a FEI QuantaTM 3D FIB (Nanofacility Piemonte, INRIM).

For characterization of the electrical properties samples have been shaped in a Hall bar geometry, 1 \div 2 cm long, 10 μ m and 50 μ m wide. The resistivity, $\rho(T)$, and the current-voltage (I-V) characteristics have been measured as a function of the temperature, in the range 4 \div 300 K, by a He closed cycle cryostat (Advanced Research System mod. 210 DE) equipped with two silicon diode thermometers (Lakeshore DT-670, one of which was calibrated with a maximum error of 6.3 mK) and a temperature controller Lakeshore mod. 332. Resistivity and I-V characteristics have been measured sourcing a constant current (Keithley mod. 220), monitored either by a pico-ammeter (Keithley mod. 6487 for $\rho(T)$) or by a multimeter (Hewlett-Packard mod. 34401 A for I-V). The voltage drop has been detected by a multimeter (Keithley mod. 2000). For the measure of $\rho(T)$ the current sourced has been in the range 1 \div 50 μ A. Depending on the kind of characterization, measures have been executed either with (e.g. I-V characteristics) or without T stabilization (e.g. $\rho(T)$). In the former case, a T stability better than 50 mK has been achieved below 15 K. In the latter approach, the variation of T during data acquisition was lower than 20 \div 30 mK. The superconducting transition temperature T_C as well as the width of the transition was measured by a liquid He-cryostat equipped with a silicon calibrated thermometer. For the determination of the upper critical magnetic field, H_{C2} , a liquid ⁴He cryostat, Oxford Instruments Teslatron 16T has been used, equipped with a superconducting magnet (up to 16T) and a variable temperature insert working from 300 K down to 1.5 K. The resistance values were measured by using either a PICOWATT AVS-47 AC or a Lakeshore mod. 370 AC resistance bridge.

Acknowledgements

We thank Antonio Bianconi, Mauro Doria and Vincenzo Lacquaniti for useful discussions. We acknowledge the collaboration with Federica Celegato for AFM analysis and Sara Quercetti for the electrical properties characterization. A.P. and N.P. acknowledge financial support from University of Camerino FAR project CESEMN. We also acknowledge the collaboration within the MultiSuper International Network (<http://www.multisuper.org>) for exchange of ideas and suggestions.

Author Contributions

N.P., A.P. and N.D.L. conceived the experiments. M.F. and N.D.L. fabricated samples. N.P., S.J.R., M.F. and C.C. conducted the experiments, N.P., A.P., L.F. and M.V.M. analysed the results. All authors reviewed the manuscript.
