**ABSTRACT** Supercapacitors are becoming increasingly important storage system components. To effectively control their terminal voltage, even in real time, numerous circuit models capable of faithfully simulating their behavior in energy systems and various applications are being explored. The three-branch supercapacitor model appears to be a good compromise between simplicity and accuracy. Typically, this model lacks accuracy in dynamic cycling and long stand-by periods. In this study, a new model identification method based on the state equations of the circuit is described and tested on a 400 F supercapacitor, and the obtained results are validated by measurements. Such an approach, suitably optimized, provides good agreement with the measurements, with discrepancies below 50 mV even in repeated cycles. In the static identification, after 90 minutes of self-discharge, the discrepancy was approximately 5 mV. The study also discusses the sensitivity of the model output to the circuit parameters, which is useful for choosing the appropriate timespan for parameter optimization and introduces variable leakage resistance and a method for its determination. Through this parameter, good agreement with the measurements is observed during the long self-discharging phases. A discrepancy of less than 50 mV between the measured and computed results is observed after one week. The union of the circuit state equations based model and the nonlinear leakage resistance determination allows the three-branch circuit model to achieve a high accuracy both in real-time simulation and in the presence of long stand-by phases.

**INDEX TERMS** Analytical modeling, Circuit optimization, Current measurement, Energy storage, Resistance, Supercapacitors, Voltage measurement.

## I. INTRODUCTION

Approximately 25 years after their entry into the market, supercapacitors (SCs) have emerged as a pervasive technology. Over the past three decades, battery energy density has grown significantly, tripling its capacity. SCs have experienced an astonishing 20-fold increase in energy density, reaching up to 100 Wh/kg in the case of hybrid capacitors [1]. With regard to power density, both batteries and SCs undergo a similar, impressive 24-fold increase [1], with SCs having far superior performance. SCs can be a better choice than batteries in high-power density applications with typical charging time scales of a few tens of seconds to a few minutes, as well as in low energy density applications and low temperature environments [2]. The most promising applications are in their integration with batteries, where the SCs provide the required power

bursts or cope with quick energy recovery [3]-[10], especially in cyclic operations such as braking and accelerating in electric vehicles (EVs). Such applications are numerous to the extent that name them all would take too many rooms. SCs applications range from uninterrupted power supplies (UPSs), cordless screwdrivers, digital cameras to provide flashlights, portable speakers, and hybrid vehicles requiring stop and go driving, including buses, trains, agricultural machinery, excavators, cranes, and forklifts [11]. Other applications include fast charging for EVs, sensor networks, emergency door operation and eviction slide operation (e.g., in the Airbus A380 jet), emergency power system of More-Electric Aircraft, flexible and wearable SCs, powering in robotics, integrated systems for renewables and energy

devices, electric unmanned aerial vehicle applications and so forth [11] - [14].

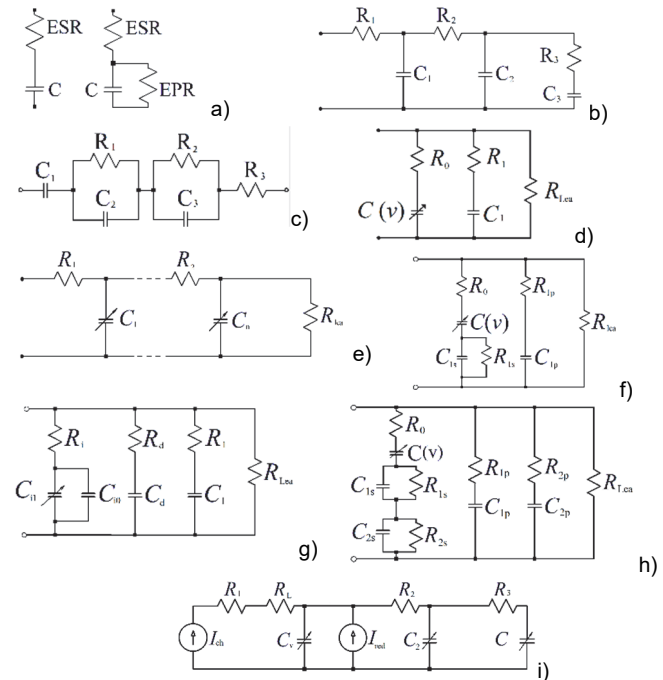

The use of SCs in real-time applications in electronic circuits requires a circuit model to correctly predict their behavior. Although for rough sizing in power systems, a linear representation with an RC circuit may be sufficient, especially when integrated into a broader control system [15]–[22], this approach is inadequate for designing electronic systems, particularly when the SCs operate intermittently, with longer stand-by periods; for example, when SCs are the storage component in power systems for sensor networks. Manufacturers generally provide only nominal resistance and capacitance parameters but not equivalent circuits. As discussed in the next section, there are numerous equivalent circuit models and methods for determining them in the literature. However, some require time-consuming procedures that are difficult to implement by designers, others show a lack of accuracy, and in a few studies, it is not clear how to identify some parameters. This study provides a novel identification procedure for a three-branch model based on circuit state equations combined with Conventional Trust Region Reflection (CTRR) optimization. The results are compared with a simple optimization of the approach proposed in [22], which has become a reference in the literature. In addition, this work proposes a novel method to evaluate the leakage resistance behavior as a function of time and voltage, enabling good correspondence between the model and measurements during prolonged stand-by periods.

## II. EQUIVALENT CIRCUIT MODELS IN LITERATURE

Multiple approaches for modeling SCs have been presented in the literature. A comprehensive review of the metrics, mechanisms, and models of SCs can be found in [23]–[29], and electrochemical models, intelligent models, and thermal models are not mentioned here but can be found in the cited papers, for example, [23], [24], [30]. Another alternative to equivalent circuit models (ECMs) are the fractional-order models. With a different mathematical approach, they exhibit good capabilities of fitting experimental data with fewer model parameters. Examples are reported in literature following time domain [31]–[35] or frequency domain approaches [36], [37].

In the following, the authors would like to recall the main ECMs approaches for reader convenience.

The one branch model is shown in Fig. 1 a), whereas Fig. 1 b) and Fig. 1 c) show a three-stage ladder model [38] and the so-called dynamic model [39], respectively. A comparison between these three models is discussed in [40]. The one-branch model is suitable for a rough design of storage systems but lacks the accuracy required to properly reproduce the behavior of SCs. Fig. 1 d) shows the two-branch model analyzed in [41] and [42]. In [43] the authors proposed an optimization of a two-branch equivalent circuit that matches the experimental data with

**FIGURE 1.** Equivalent circuit models of SCs: a) one branch model, b) three-stage ladder model, c) dynamic model, d) two-branch model, e) transmission line model, f) modified two-branch circuit, g) three-branch Zubieta-Bonert model, h) De Carne and colleagues' model, i) Torregrossa and colleagues' model.

a mean relative discrepancy ranging from 0.5 % to 4 %, depending on the current. The transmission line model is a generalization of the three-stage ladder model, as shown in Fig. 1 e). In [26], the authors compared three models: i) the RC model, ii) the two-branch model, and iii) a multi-branch model with respect to the experimental results shown in [44]. The comparison reveals that the multi-branch model better satisfies the experimental results. Fig. 1 f) shows a modified two-branch circuit [45] while Fig. 1 g) is the well-known three-branch Zubieta-Bonert model [22]. Fig. 1 h) represents a combination of configurations 1 f) and 1 g), which is particularly suitable for real-time modeling [46]. Generally, the models are designed to identify the 'trained' SC. In fact, a new SC exhibits a different behavior than an 'operating' SC, as shown in Fig. 2.

**FIGURE 2.** 'Training' of a new 400 F supercapacitor to reach a stable output voltage.

Similarly, when a SC undergoes a very long stand-by phase or remains unused for a long time, its behavior resembles that of a non-trained SC. In fact, the charge accumulated in the macropores available at the electrode–electrolyte interface increases with each charge cycle until it reaches saturation. Moreover, the charging time at the same current slightly reduces charging after charging. As shown in Fig. 2, it takes approximately ten charging cycles, or even fewer, to reach saturation [47]. Likewise, if a SC remains inactive for a long time, it undergoes a relaxation and redistribution phenomenon, resulting in a lower output voltage during self-discharge compared to a trained capacitor. This phenomenon is analogous to the one described earlier. The model proposed in [47] and shown in Fig. 1 i) incorporates this phenomenon, together with [48], which however follows a different approach.

The analysis in this study refers to trained SCs. The model is built for a SC that starts from a known and possibly repeatable condition, to then be controlled over time. Once training has been carried out on the SC, possibly repeated after a long period of relaxation, so that the charge-self discharge cycle is repeatable, a reference condition is defined. Parameters of the proposed ECM are defined in this condition.

### III. MEASUREMENT SETUP

The present study utilizes current and voltage measurements on a SC to identify and verify the proposed models. The current measurement is performed with a LEM IT\_65-S Ultrastab transducer, with an expanded uncertainty limited to 0.1 % in DC. Two channels of a National Instruments PXI-4461 board, fitted with a delta-sigma analog-to-digital converter at 24 bits, were used as digitizers. The voltage is measured directly on one channel of the board with a voltage range of  $\pm 3.16$  V. Measurements are acquired and managed using a program created in the LabVIEW environment. For a long stand-by of a few days or a week, voltage measurements were performed with a reference multimeter (Fluke 8588 A) with an input impedance greater than 10 G $\Omega$  and sampling interval of 10 s. The instrumentation was calibrated at INRIM before the measurements. To provide a constant charging and discharging current, an ITECH IT-6015-C bidirectional programmable DC power supply is implemented in the experimental setup. All measurements and investigations were performed at a controlled room temperature of  $23 \pm 0.5^\circ\text{C}$ . The device under test (DUT) is an EDLC Eaton XV series SC with a nominal capacitance of 400 F. The following results are obtained with a charging current of 15 A.

### IV. THREE-BRANCH EQUIVALENT CIRCUIT

The three-branch equivalent circuit can provide an excellent simulation of the behavior of SCs with limited complexity. Unlike the two-branch approach, the three-branch circuit allows the simulation of real-time behavior over a long

**FIGURE 3.** 'Three-branch equivalent circuit of a SC.

timespan. For parameter identification through a charging and self-discharging phenomenological approach, we can refer to Fig. 2. The SC is charged with a constant current  $i$  up to the rated voltage (voltage peak); subsequently, the charging current drops to zero, and the SC undergoes a self-discharging phase, mainly owing to the relaxation and charge redistribution phenomena. The three-branch model proposed in [22] is illustrated in Fig. 3. Each branch has its own time constant. To simulate nonlinear charging behavior (Fig. 2), a voltage-dependent capacitor is introduced. The first, second, and third branches are called immediate, delayed, and long-term branches, respectively, based on their time constants.

The first or immediate branch with parameters  $R_i$ ,  $C_{i0}$ , and the voltage-dependent capacitor  $C_{i1}$  mainly influences the charging phase within a time range of tens of seconds. The second or delayed branch with parameters  $R_d$  and  $C_d$  mainly influences the initial part of the discharging phase (usually lasting a few minutes), and the third or long-term branch with parameters  $R_l$ ,  $C_l$  represents the SC behavior in the latter part of the discharging phase, which lasts a few hours. When the three branches reach equilibrium, output voltage  $V_i$  no longer changes. To simulate further discharge of the SC, which occurs in the real world, a leakage resistor  $R_{lea}$  is added in parallel to the terminal voltage. This qualitative explanation does not properly describe the interdependence between the three branches, as discussed in Section VI B. For what concern  $R_{lea}$ , to the best knowledge of the authors, there are limited references in the literature describing a method to assess this parameter [49]. A novel method is proposed in this study and is described in Section V. Furthermore, this involves a significant modification of the equivalent circuit of Fig. 3 with respect to the classic circuit shown in Fig. 1 g), as  $R_{lea}$  is no longer a constant resistance but a variable resistance dependent on the voltage.

However, by neglecting  $R_{lea}$  as a first approximation, an easy estimation of the other seven circuit parameters in Fig. 3 can be obtained according to [22]. As also verified by other authors (e.g., [47] and [50]), the approach proposed in [22] tends to underestimate the final voltage of the SC in the charging phase; therefore, at least optimization of the first branch parameters is required to improve the accuracy.

A simple and effective optimization can be achieved as follows. The voltage on the first branch capacitors can be expressed as

$$V_i(t) = \frac{Q_i(t)}{C_i} = \frac{\int_0^t i_i dt}{C_{i0} + C_{i1} V_i} = \frac{i_i t}{C_{i0} + C_{i1} V_i} \quad (1)$$

so

$$C_{i1} V_i^2(t) + C_{i0} V_i(t) - i_i t = 0 \quad (2)$$

where  $Q_i(t)$  is the charge stored in the SC versus time and  $t$  is the time. The objective function to be minimized is the difference between the measured terminal voltage  $V_{tmeas}(t)$  and that obtained by the model  $V_t$ , as follows:

$$V_t = V_i + R_i i_i \quad (3)$$

Therefore, by obtaining  $V_i(t)$  from (2), where only the positive solution has a physical meaning, and substituting in (3), the objective function  $f_{obj}(t)$  is defined as:

$$f_{obj}(t) = V_{tmeas}(t) - \frac{(-C_{i0} + \sqrt{C_{i0}^2 + 4C_{i1}i_i t})}{2C_{i1}} - R_i i_i \quad (4)$$

Starting from the initial parameters  $z_0 = (C_{i0}, C_{i1})_0$  identified according to [22], the function  $f_{obj}(t)$  is nonlinear. Therefore, a nonlinear minimization approach is required to optimize the vector parameter  $z = (C_{i0}, C_{i1})$ . This can be achieved by solving a nonlinear least-squares problem, where  $f_{obj}(t)(z)$  is a vector, with  $n$  elements being the function values at each measured time sample  $V_{tmeas}(t)$ . So that:

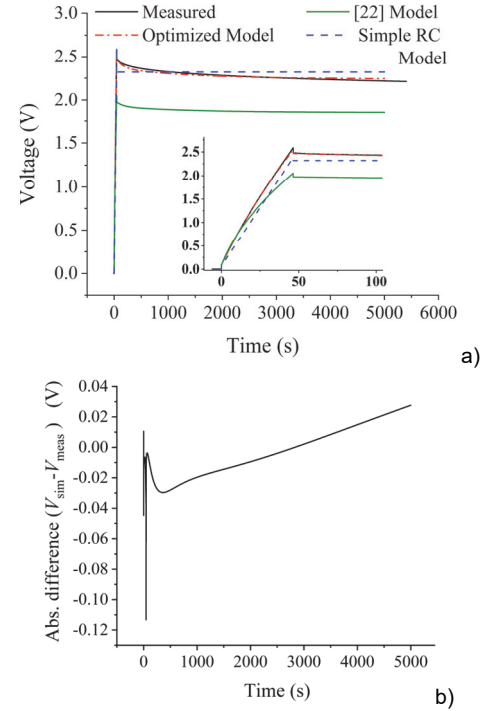

$$f_{obj}(z) = \begin{bmatrix} f_{obj1}(z) \\ f_{obj2}(z) \\ \vdots \\ f_{objn}(z) \end{bmatrix} \quad (5)$$

The nonlinear least-squares problem can be solved efficiently in the Matlab<sup>TM</sup> environment using the 'lsqnonlin' function, according to the command:  $z = \text{lsqnonlin}(f_{obj}(z), z_0)$ . As the output, the function returns the optimized parameters  $z_{opt} = (C_{i0\_opt}, C_{i1\_opt})$  with a CPU time lower than one second, on a common personal computer.

A comparison between the measured values and those obtained using the optimized model is shown in Fig. 4 a). In the same figure, the results of the one-branch model and of the model [22] are also shown for completeness. Fig. 4 b) shows the absolute voltage difference between the measured and computed values using the optimized model. The maximum discrepancy of 0.11 V, corresponding to a relative difference of 4 % with respect to the rated voltage, occurs when the voltage peak drop is reached, and is mainly due to a time-shift introduced by the model. Except for this peak error, in most of the considered timespan, the error does not exceed 1.5 % ( $\pm 0.04$  V). After a few hundred seconds, the error shows an increasing trend with time. Indeed, as underlined by other authors, the model does not seem to be suitable for long stand-by phases of the SC. To overcome this problem, a new high-accuracy modeling approach is proposed in Section VI A, along with an improvement in the  $R_{lea}$  assessment described in the next section.

## V. LEAKAGE RESISTANCE ASSESSMENT

Following the charging of the SC, once the nominal voltage is reached and the charging current ceases, a self-discharge process occurs, which can be divided into three parts. In the

**FIGURE 4.** 'a) Comparison between the measured galvanostatic charging and self-discharging for the: i) one-branch model (simple RC), ii) [20] model, and iii) optimized model. b) Absolute difference between the measured voltage and the one computed through the optimized [20] model.

**FIGURE 5.** 'Computed behavior of the SC terminal voltage  $V_i$  during charging and self-discharging lasting 6 hours. The figure shows also the behavior of the voltages of the capacitors  $C_{i0}$  and  $C_{i1}$  ( $V_i$ ),  $C_d$  ( $V_d$ ), and  $C_i$  ( $V_i$ ) of the equivalent circuit (Fig. 3). A 400 F SC was considered.

first part, there is a sudden voltage decrease near the peak, lasting a few milliseconds to tens of milliseconds, corresponding to the voltage drop in the internal resistance when the current ceases. Then, in the second part, the voltage decreases owing to the charge redistribution between the three branches of the equivalent circuit, which lasts for approximately a few hours (Fig. 5). Finally, in the long-lasting third part (which can extend for many hours or even days), the voltage decreases owing to the internal electrochemical phenomena. The last part is considered in the model by the leakage resistance  $R_{lea}$  which is simply a representation of the phenomenon, even if its physical/chemical nature is likely not

only resistive. Indeed,  $R_{leak}$  must be a nonlinear parameter to properly mimic the SC behavior under self-discharge. In the model without  $R_{leak}$ , the voltage remains constant indefinitely, which is not physically reasonable.

Starting from a discharged SC, we can define the time from the beginning of the SC charging, up to the time where the equilibrium between the internal capacitances is reached, as 'settling time' (ST). This time is approximately 4 hours for the considered DUT (Fig. 5). For a specific SC, the ST can be verified using the SC model described in Section VI.

To determine  $R_{leak}$  for our DUT, we implemented a method that consists of charging the SC up to the rated voltage and then leaving it self-discharging for three days by recording the terminal voltage  $V_{t1}(t)$ . After three days, the charging and discharging procedure is repeated, and the terminal voltage  $V_{t2}(t)$  is measured and recorded for a couple of days by connecting a 10 k $\Omega$  auxiliary resistor,  $R_{aux}$ , in parallel with the SC. Discharging is quicker as the resistance decreases. A very important point is to connect the auxiliary resistor after approximately twice the ST, because before this time, the effect of the third branch of the equivalent circuit could still be present, which can interfere with the effect of  $R_{leak}$ .

$R_{aux}$  can be chosen in order to significantly affect the voltage variation versus time, while avoiding a too quick discharge.

The experimental results are shown in Fig. 6 a). The blue curve represents the discharge of the SC alone ( $R_{leak}$ ), which is properly fitted by an exponential decay function with three time constants:

$$V_{t1}(t) = V_{01} + a_{11}e^{-\frac{(t-t_{11})}{\tau_{11}}} + a_{12}e^{-\frac{(t-t_{11})}{\tau_{12}}} + a_{13}e^{-\frac{(t-t_{11})}{\tau_{13}}} \quad (6)$$

where  $\tau_{11}$ ,  $\tau_{12}$  and  $\tau_{13}$  are three time constants and  $V_{01}$ ,  $a_{11}$ ,  $a_{12}$ ,  $a_{13}$  and  $t_{11}$  are the other interpolation parameters.

The green curve represents the discharging of the SC with auxiliary resistance in parallel ( $R_{leak} // R_{aux}$ ), which is properly fitted with an exponential decay function with two time constants  $\tau_{21}$  and  $\tau_{22}$ .

$$V_{t2}(t) = V_{02} + a_{21}e^{-\frac{(t-t_{22})}{\tau_{21}}} + a_{22}e^{-\frac{(t-t_{22})}{\tau_{22}}} \quad (7)$$

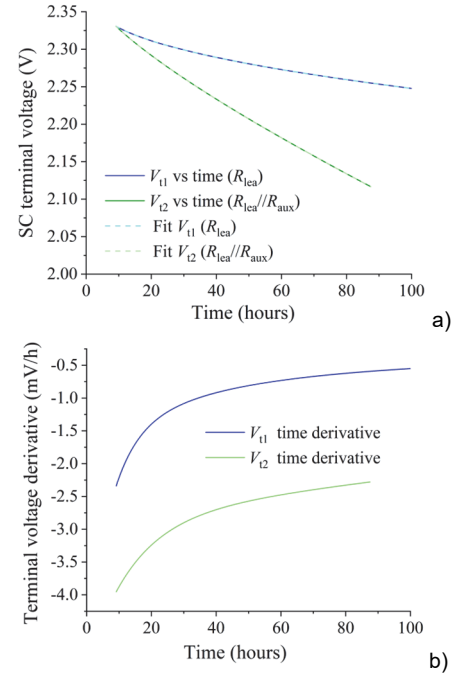

and where  $V_{02}$ ,  $a_{21}$ ,  $a_{22}$  and  $t_{22}$  are the other interpolation parameters.

In the model, the equivalent circuit seen by the output resistance  $R_{leak}$  is a voltage-dependent capacitance with a small series resistance, which is negligible compared to the output resistance. Therefore, it is reasonable to hypothesize that the rate of variation of the voltage  $V_t$  at the terminals of the SC over time depends on the self-discharge current. Without an auxiliary resistor, the self-discharge current can be expressed as

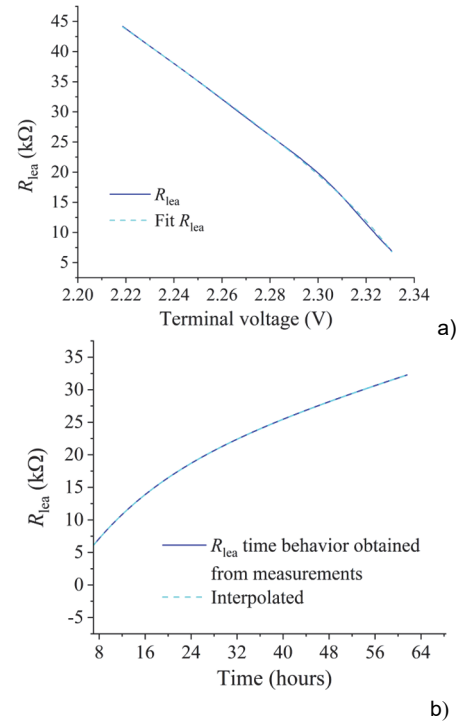

$$\frac{V_{t1}}{R_{leak}(V_{t1})} = C(V_{t1}) \left. \frac{dV_{t1}(t)}{dt} \right|_V \quad (8)$$

and in presence of the auxiliary resistor, it can be obtained in accordance with

$$\frac{V_{t2}}{\frac{R_{leak}(V_{t2}) R_{aux}}{R_{leak}(V_{t2}) + R_{aux}}} = C(V_{t2}) \left. \frac{dV_{t2}(t)}{dt} \right|_V \quad (9)$$

**FIGURE 6.** a) SC long term self-discharging behavior. Blue line: self-discharging. Green line: self-discharging with an auxiliary resistor in parallel. b) Time derivatives of the curves in Fig. 6 a).

**FIGURE 7.** Leakage resistance behavior of a 400 F SC a) versus the SC terminal voltage and b) versus time.

The time behavior of the voltage derivatives is shown in Fig. 6 b). To evaluate the output resistance, (8) and (9) must be considered at the same voltage (i.e., by horizontal lines in Fig. 6 a), because in this case, the capacitance seen by the

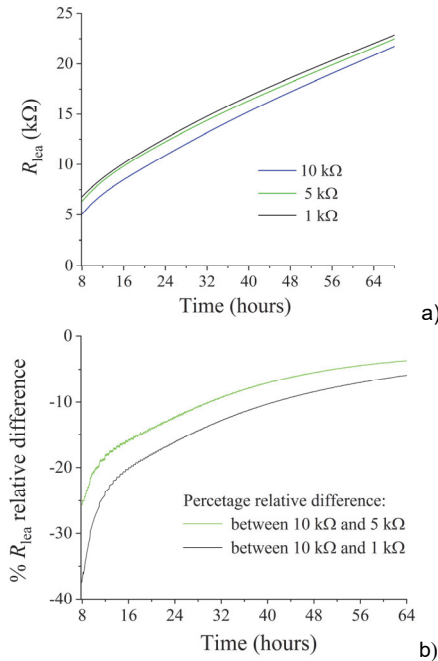

output resistance is the same. The same voltage is obtained at different time instants, where we call  $t_{lea}$  the instant in which a specific voltage  $V_{t1}$  is obtained with only  $R_{lea}$ , and  $t_{aux}$  when the same voltage  $V_{t2}(t_{aux}) = V_{t1}(t_{lea})$  is obtained in the case of  $R_{lea} // R_{aux}$ . At the evaluation points, the voltage is the same, and the ratio between (9) and (8) is simplified as

$$R_{lea}(V) = R_{aux} \left[ \left. \frac{dV_{t2}(t)}{dt} \right|_{t=t_{aux}} \left( \left. \frac{dV_{t1}(t)}{dt} \right|_{t=t_{lea}} \right)^{-1} - 1 \right] \quad (10)$$

The computed behavior of  $R_{lea}$  versus voltage [ $R_{lea} = R_{lea}(V)$ ] provides a function that increases as the voltage decreases, as shown in Fig. 7 a) for the considered SC. The trend is well interpolated by the function with two time constants shown in (7). Because there is a one-to-one correspondence between the voltage during discharge (blue curve in Fig. 6 a) and time, the  $R_{lea}$  time behavior [ $R_{lea} = R_{lea}(t)$ ] can be easily obtained, as shown in Fig. 7 b), which can also be useful in the simulations. The interpolation of Fig. 7 b) can be obtained with a function similar to (7), and in particular,

$$R_{lea}(t) = A_0 + A_1 e^{\left(\frac{t}{\tau_1}\right)} + A_2 e^{\left(\frac{t}{\tau_2}\right)} \quad (11)$$

where  $R_{lea} = R_{lea}(2 \cdot ST)$  is the initial value of  $R_{lea}$  that, for the considered SC, is equal to 6.06 k $\Omega$ .

**FIGURE 8.** a) Leakage resistance vs time with three different  $R_{aux}$ , b) resistance percentage relative difference with respect to determination with  $R_{aux} = 10$  k $\Omega$ .

In order to verify the pattern of  $R_{lea}$  in another SC and to verify the variation of the results changing the  $R_{aux}$  we tested a twin SC, same brand and same size, with 3 auxiliary resistors having values of 10 k $\Omega$ , 5 k $\Omega$  and 1 k $\Omega$  to cover at least one order of magnitude variation. The results are reported in figures 8 a) and 8 b). The behavior of the  $R_{lea}$  versus time is similar to the previous SC with a similar initial value, but with

a lower resistance increase versus time. Fig. 8 a) highlight that changing the auxiliary resistor the  $R_{lea}$  trend versus time remains the same, but there is a non-constant bias in terms of resistance values at a specific time, which significantly reduces versus time. With respect to the determination with  $R_{aux} = 10$  k $\Omega$ , such a bias determines a variation of the initial  $R_{lea}$  up to 37 % for  $R_{aux} = 1$  k $\Omega$  and about 25 % with  $R_{aux} = 5$  k $\Omega$ , and below 10 % after 36/42 hours (Fig. 8 b). Such a variation could seem quite high, however due to the low sensitivity of SC terminal voltages with respect to  $R_{lea}$  variations (see Sect. VI B), this does not compromise the effectiveness of  $R_{lea}$  behavior determination, as will be better discussed in Sect. VI C.

A useful choice criterion for  $R_{aux}$  could be to perform a preliminary measurement, to estimate the initial  $R_{lea}$  value, and choose a  $R_{aux}$  with a resistance value close to that.

## VI. OPTIMIZATION BASED ON STATE EQUATIONS

An alternative to the 'classical' identification presented in [22] is proposed below based on the circuit state equations. In this approach, resistance  $R_{lea}$  is considered constant to the initial value determined in the previous section.

### A. STATE EQUATIONS BASED MODEL

The vector state equation can be obtained with reference to the circuit shown in Fig. 3, as follows:

$$\dot{\mathbf{v}} = \mathbf{A}\mathbf{v} + \mathbf{b} \quad (12)$$

where  $\mathbf{v}$  is the vector representing the state variables, which are the capacitor voltages (13) and  $\dot{\mathbf{v}}$  is the time-derivative vector (14).

$$\mathbf{v} = \begin{bmatrix} V_i \\ V_d \\ V_l \end{bmatrix} \quad (13) ; \quad \dot{\mathbf{v}} = \begin{bmatrix} \frac{dV_i}{dt} \\ \frac{dV_d}{dt} \\ \frac{dV_l}{dt} \end{bmatrix} \quad (14)$$

Equation (12) is nonlinear because the matrix of coefficients  $\mathbf{A}$  depends on  $V_i$ , and  $\mathbf{b}$  is the control vector.

It is possible to start from Kirchhoff equations at circuit nodes like

$$i_l = i - i_i - i_d \quad (15)$$

and loop equations

$$\begin{cases} V_i - V_d = R_d \cdot i_d - R_i \cdot i_i \\ V_d - V_l = R_l \cdot i_l - R_d \cdot i_d \\ V_l - V_i = R_i \cdot i_i - R_l \cdot i_l \end{cases} \quad (16)$$

by considering that currents are the time derivatives of capacitors charge as:

$$\begin{cases} i_i = \frac{dQ_i}{dt} = C_i(V_i) \cdot \frac{dV_i}{dt} \\ i_d = \frac{dQ_d}{dt} = C_d \cdot \frac{dV_d}{dt} \\ i_l = \frac{dQ_l}{dt} = C_l \cdot \frac{dV_l}{dt} \end{cases} \quad (17)$$

Concerning the first equation in (17) we can better specify that:

$$i_i = \frac{d}{dt} [(C_{i0} + C_{i1} V_i(t)) V_i(t)] = C_{i0} \frac{dV_i}{dt} + 2 C_{i1} V_i \frac{dV_i}{dt}$$

so that  $C_i(V_i)$  is:

$$C_1(V_i) = C_{i0} + 2 \cdot C_{i1} \cdot V_i \quad (18)$$

Combining (15) and (16), one can obtain the currents as a function of the state variables, of the resistances, and of the total input current  $i$ . By substituting the right side of (17) to currents, matrix  $A$  and vector  $b$  can be easily computed as follows:

$$A = \begin{bmatrix} \frac{-(R_d + R_l)}{\text{den} \cdot C_1(V_i)} & \frac{R_l}{\text{den} \cdot C_1(V_i)} & \frac{R_d}{\text{den} \cdot C_1(V_i)} \\ \frac{R_l}{\text{den} \cdot C_d} & \frac{-(R_l + R_i)}{\text{den} \cdot C_d} & \frac{R_i}{\text{den} \cdot C_d} \\ \frac{R_d}{\text{den} \cdot C_l} & \frac{R_i}{\text{den} \cdot C_l} & \frac{-(R_i + R_d)}{\text{den} \cdot C_l} \end{bmatrix} \quad (19)$$

$$b = \begin{bmatrix} \frac{R_d \cdot R_l \cdot (i - i_{lea})}{\text{den} \cdot C_1(V_i)} \\ \frac{R_l \cdot R_i \cdot (i - i_{lea})}{\text{den} \cdot C_d} \\ \frac{R_i \cdot R_d \cdot (i - i_{lea})}{\text{den} \cdot C_l} \end{bmatrix} \quad (20)$$

where:

$$\text{den} = R_i \cdot R_l + R_i \cdot R_d + R_d \cdot R_l \quad (21)$$

When (12) is solved, the SC terminal voltage can be obtained as (22).

$$V_t = \frac{R_d R_l V_i + R_l R_l V_d + R_i R_d V_l + R_i R_d R_l (i - i_{lea})}{\text{den}} \quad (22)$$

## B. SENSITIVITY ANALYSIS

Starting from the state equations based model, a sensitivity analysis was performed by varying one circuit component value (resistance or capacitance) at a time of  $\pm 5\%$  and  $\pm 10\%$  with respect to the identified nominal value in the considered DUT. The variations in the SC terminal voltage owing to the variations in the resistance and capacitance values are shown in Fig. 9. From this analysis, some interesting clues can be deduced regarding the sensitivity of the model output to the circuit parameters and the choice of an appropriate timespan for parameter optimization. Fig. 9 a) shows the variation in the SC terminal voltage  $V_t$  owing to the relative variation in the input resistance  $R_i$  and clearly shows that the variation in the voltage is associated with the variation in the input current. Fig. 9 b) shows the effect of  $R_{lea}$  variations on the terminal voltage. As shown, the variations in  $R_{lea}$  affect the output voltage less significantly than the other parameters, but its influence increases with time. However, if  $R_{lea}$  is not properly chosen or measured and its order of magnitude is incorrect, it can have a significant effect on the identification of the other parameters. Fig. 9 c) and Fig. 9 d) show the variation in the SC terminal voltage owing to the relative variation in  $C_{i0}$  and  $C_{i1}$ . The sensitivity is very high compared with that of the other parameters. This variation is prevalent during the charging phase of the capacitor. The concavity of the variations for these two parameters is opposed, which is appropriate for optimization. Therefore, from the sensitivity analysis, a suitable timespan for the optimization of these two parameters can be approximately equal to the SC charging time of the

equivalent circuit first branch. Fig. 9 e) show the variation in the SC terminal voltage owing to the relative variations in the resistance  $R_d$ . In this case, the sensitivity is more than one order of magnitude lower than that of the previous branch and the effect is maximum after the voltage peak and become negligible in about a half of the settling time.

Fig. 9 f) show the variation in the SC terminal voltage owing to the relative variations in the resistance  $C_d$ . Also in this case, the sensitivity is about one order of magnitude lower than that of the first branch parameters and the effect is maximum in about one third of the settling time and then remains almost constant, with a slow decrease. Fig. 9 g) and Fig. 9 h) show instead the variation of the SC terminal voltage due to the relative variation of the resistance  $R_l$  and the capacitance  $C_l$ , respectively. Here the initial shape of the graph is similar to those of  $R_d$  and  $C_d$ , but the time is expanded to about one order of magnitude. The sensitivity is comparable to the other one and, as in the previous case, the sensitivity for the resistance has a sign that is opposed to that of the capacitance.

The different behaviors in time and shape of these graphs, and their similar sensitivities, allow us to consider the optimization of  $R_d$ ,  $C_d$ ,  $R_l$  and  $C_l$ , with a proper choice of the timespan, approximately from the end of the charging of the first branch to the end of the ST of the capacitances  $C_d$  and  $C_l$  (e.g., from 2 minutes to 4 hours in Fig. 5).

## C. MODEL IDENTIFICATION

Model identification is performed by comparing the model results and experimental measurements within a timespan that is limited but sufficient to allow each of the three branches to affect the terminal voltage of the SC. In our experiments, we verified that one-third of the ST is sufficient for a good model identification.

The optimization is obtained using the objective function, which is the difference between the voltage at the terminals of the SC simulated by the model  $V_t(t)$  and that measured in the laboratory at the SC terminals  $V_{tmeas}(t)$ . In addition to the objective function, the optimizer requires some other input data: i) the model equations (matrix  $A$  and vector  $b$ ), ii) an initial value of the parameters to be identified ( $R_d$ ,  $R_l$ ,  $C_{i0}$ ,  $C_{i1}$ ,  $C_d$ ,  $C_l$ )<sub>0</sub>, iii) the initial value of  $R_{lea}$  and of the state variables ( $V_i$ ,  $V_d$ ,  $V_l$ )<sub>0</sub>, and iv) the value of  $R_i$ .

The nonlinear optimizer that we found effective is based on the family of CTRR algorithms [51],[52]. If the optimization algorithm reaches the convergence threshold set by the user, optimized parameters are provided.

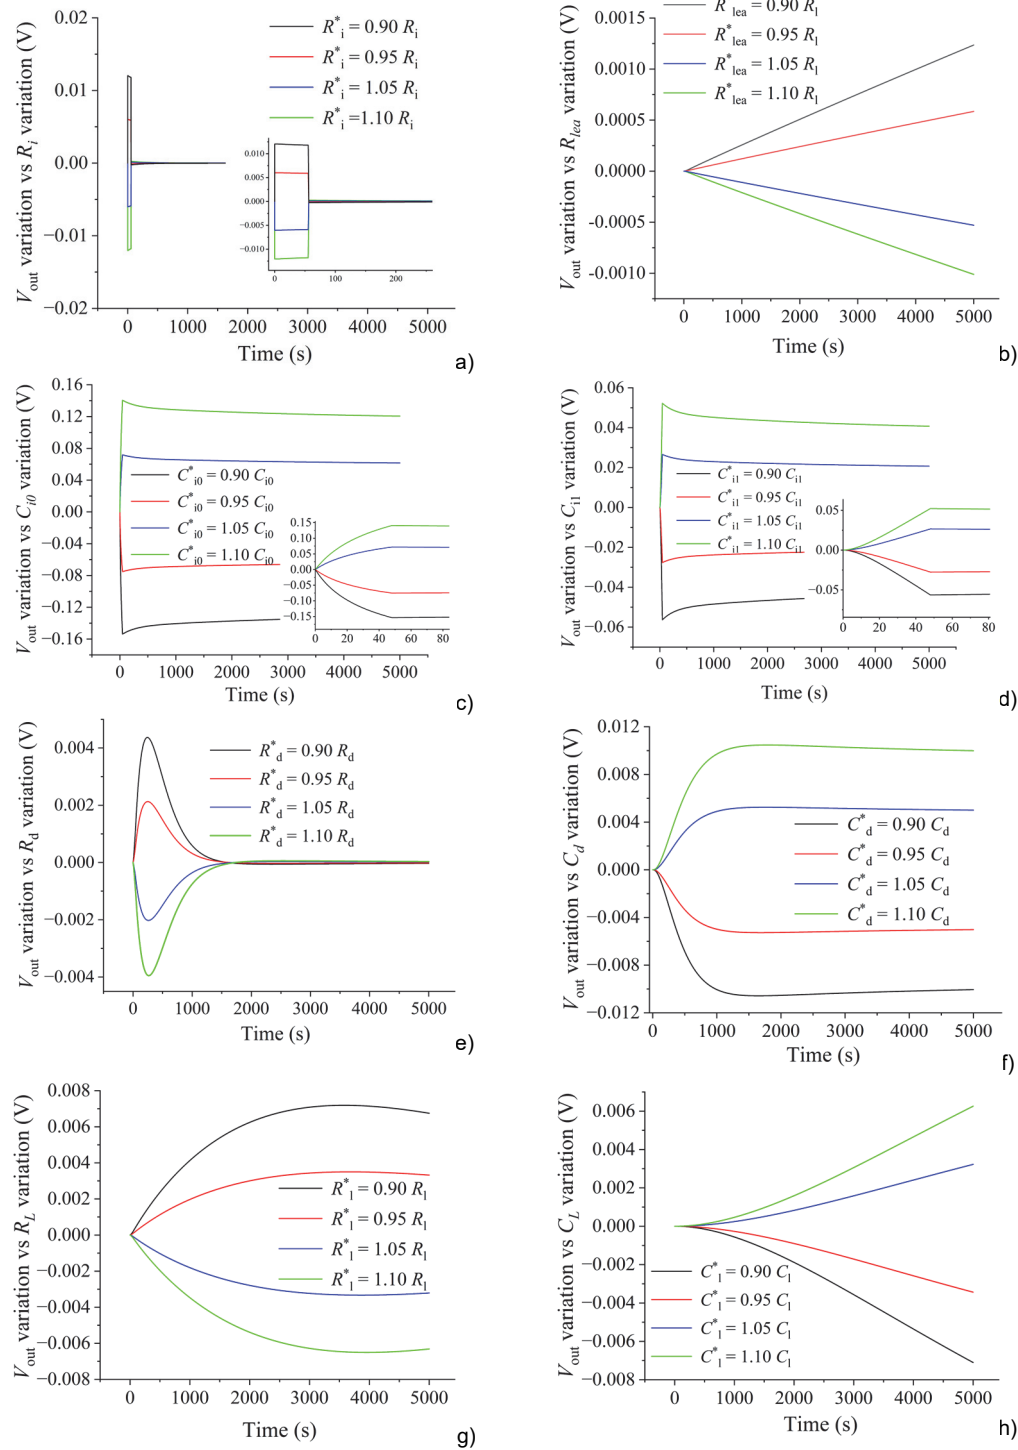

A discussion of the optimization algorithm is beyond the scope of this study. Here it is enough to say that there is an efficient tool in Matlab™ for this type of optimization which is the "estimate nonlinear grey-box model parameters" which responds to the command 'nlgreyest' and that can solve the optimization problem summarized in Fig. 10.

Two clarifications regarding the initial parameters, in point ii) above, it is noted that resistance  $R_i$  is missing.  $R_i$  is defined as in [22] by the voltage and current ( $V_l$ ,  $i_{ch}$ ) at  $t_1 = 20$  ms from

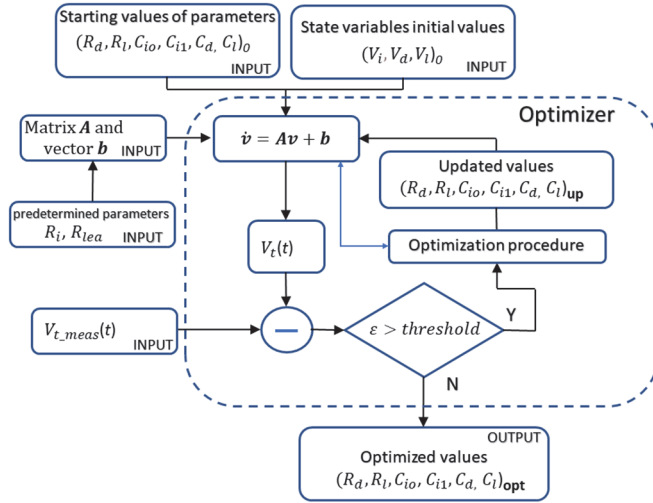

the starting time in the charging phase of a trained SC, according to:

$$R_i = \frac{V_i}{i_{ch}} \quad (23)$$

**FIGURE 9.** Absolute variation ( $V_i - V_i^*$ ) of the SC terminal voltage  $V_i$  induced by a variation  $\pm 5\%$  and  $\pm 10\%$  of the following parameters: a)  $R_i$ , b)  $R_{lea}$ , c)  $C_{i0}$ , d)  $C_{i1}$ , e)  $R_d$ , f)  $C_d$ , g)  $R_l$ , and h)  $C_l$ , respectively.

**FIGURE 10.** Basic scheme of optimization based on state equations. Optimal parameters search is based on CTRR optimization.

Regarding the other parameters, it is not necessary to have particularly accurate initial parameters; however, coarse parameters are sufficient for convergence of the algorithm. Prior identification of the parameters, as in [22], is not necessary. Finally, regarding point iii) mentioned above, for the trained and discharged SC, the initial values of the state variables are equal to zero, and the initial value of  $R_{lea}$  must be identified according to Section V.

A point worth of attention is the presence of a bias in the measured current, which is the input for the model, together with the measured voltage at the SC terminals,  $V_t$ . Even a very small bias of a few milliamperes when the current approaches zero can provide significant variations in the model results.

## VII. SC BEHAVIOR: SIMULATION AND VALIDATION

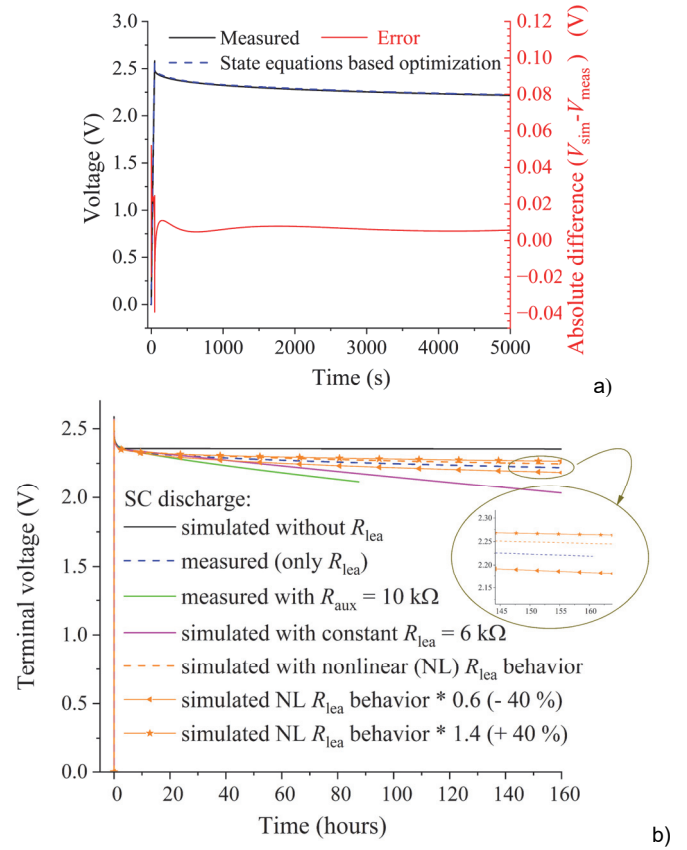

The state equations based model was used to identify the model of the DUT already considered in Sections IV and V, and its parameters are listed in Table I.

TABLE I

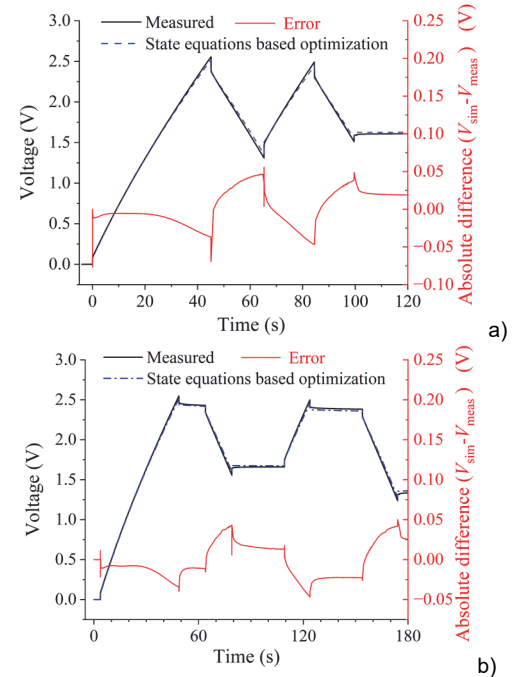

400 F SC EQUIVALENT CIRCUIT PARAMETERS

$R_l$ (mΩ)	$C_{j0}$ (F)	$C_{il}$ (F)	$R_d$ (Ω)	$C_d$ (F)	$R_l$ (Ω)	$C_l$ (F)
5.69	261.6	33.05	12.74	11.77	189.1	13.43

Fig. 11 a) shows the identification results, where the absolute error, calculated as the difference between the terminal voltage computed by the model and that measured, does not exceed 50 mV around the voltage peak, and then settles to values ten times lower. It should be noted that unlike the identification performed in Section IV (Fig. 4 b), the error does not increase significantly over time. For longer stand-by periods, the previously computed behavior of  $R_{lea}$  versus time, as shown in Fig. 7 b), is included in the model. As highlighted in Fig. 11 b), the trend of  $V_t$  computed with the nonlinear  $R_{lea}$  behavior is very close to the measured one, with discrepancies not exceeding 50 mV. It was pointed out in Sect. V that the determination of  $R_{lea}$  nonlinear behavior is affected by a

**FIGURE 11.** Comparison between the voltage measured at the SC terminals and the one computed with the three-branch model identified through the state equations based optimization. The discrepancy ('error') is also shown. a) Static model with constant  $R_{lea}$ , b) long term model with variable  $R_{lea}$ .

**FIGURE 12.** Comparison between the SC voltage computed and measured for a) a first sequence and b) a second sequence with stand-by phases. The absolute discrepancies between measured and computed results ('error') are also shown.

significant uncertainty and measurements in Sect. V highlighted variations up to about 40 % in the initial  $R_{leak}$  values which are dependent on the choice of the  $R_{aux}$ . Due to the small sensitivity of the terminal voltage with respect to  $R_{leak}$  variations, as highlighted in Fig. 11 b), a variation of  $\pm 40\%$  in the  $R_{leak}$  nonlinear behavior lead to a discrepancy lower than 50 mV with respect to the measured values ( $< 2\%$ ).

The same diagram, on the contrary, highlights that the results obtained with constant  $R_{leak}$  shows clearly bigger discrepancies and are less reliable.

Figures 12 a) and 12 b) show how, even under dynamic conditions, without (Fig. 12 a) or with (Fig. 12 b) a significant stand-by phase, the absolute error with respect to the measurements remains limited to 50 mV.

## VIII. CONCLUSION

This paper proposes a method to accurately identify the three-branch equivalent circuit of SCs. In particular, a novel method for the determination of the variable leakage resistance in the SC model is proposed and implemented. The method requires a preliminary determination of the initial values of leakage resistance and internal resistance  $R_i$ . The  $R_{leak}$  behavior is determined with a measurement procedure that uses an auxiliary resistor. Subsequently, through an optimized approach based on the state equations, other circuit parameters are identified. This approach guarantees a good simulation of the SC behavior for the timespan defined by the ST, which is related to the charging time of the third branch. For a longer timespan, basically from twice ST on, the nonlinear time behavior of  $R_{leak}$  must be measured and implemented in the model. This allows for high accuracy, even for long stand-by phases lasting for several days. The assessment of a nonlinear  $R_{leak}$  could be useful also for other ECMs when the effect of the circuit capacitor voltages reaches an equilibrium, and the further discharging of the device need to be simulated by the presence of a leakage resistance.

**Mauro Zucca** studied at Politecnico di Torino, where he graduated in 1994 and obtained the PhD in Electrical Engineering in 1998. He achieved the qualification as associate university professor in Electrical Engineering in 2012. Dr. Zucca is currently chief of the "Electromagnetic fields and systems" group at INRIM. Since 2017 he is Senior Researcher. His papers have more than 960 citations ( $H_{\text{index}}$  19). He participated in over 100 conferences, 10 of which by invitation and is the author of over

90 publications in international peer-review journals. His activity includes the study and design of electromagnetic devices, storage, shielding of power systems, inductive charging. He was responsible for 8 research contracts participated in 15 collaborative research projects: in 3 of them as Principal Investigator. He is co-author of three patents and a commercial software for computational electromagnetics. He is member of the Technical Committee TC106 of the Italian Electrotechnical Committee (CEI) and IEEE Senior member.

**Melika Hassanzadeh** received the B.S. and M.Sc. degrees in Electrical Engineering from Babol Noshirvani University of Technology, in Babol, Iran, in 2011 and 2014, respectively. She is currently a PhD student in Metrology at Politecnico di Torino, Italy, and is performing her activity research at INRIM. Her research focus is on the modeling of supercapacitors, and she has experience both in modeling and software development and in laboratory practice, including signal generation,

conditioning, and acquisition. She is currently participating in the EU research project Emphasis dealing with SCs.

**Ornella Conti** was born in Viterbo (Italy) in 2001. She received a bachelor's degree in Electrical Engineering from Politecnico di Torino in 2023. She was selected at Politecnico to follow the "Path for enterprising students". She was involved in a long internship at INRIM working on supercapacitor characterization and contributed to extensive experimental testing of different devices, including model validation.

**Umberto Pogliano** was born near Turin, Italy, in 1950. He has received the Dr. Ing. degree in Electronic Engineering in 1975 and a PhD degree in Metrology in 1987, both from the Politecnico di Torino.

In 1977 he joined the Electrical Metrology Department of the Istituto Nazionale di Ricerca Metrologica (INRIM), Turin, where his research activity focused on the development of systems and procedures for precision DC and AC low-frequency measurements. His main interests were in the AC-DC transfer standard, in the AC voltage, current and power measurements, and in the generation, acquisition, and reconstruction of electrical signals. Since 2015, he has retired, but still cooperates as a metrology expert in some INRIM projects and activities.
